

Econ 244 - Homework #4

1) (CRE vs Fixed Effects)

- (a) Prove that the LSDV estimator of this model is consistent for β :

The LSDV estimator is given estimating

$$Y_{it} = \sum_{j=1}^N \gamma_j D_{it}^j + \beta X_{it} + \epsilon_{it}$$

By the Frisch-Waugh-Lovell theorem, the estimated coefficient β is equivalent to regressing \tilde{Y}_{it} on \tilde{X}_{it} , \tilde{Y}_{it} and \tilde{X}_{it} are the regressions of Y and X on the dummy variables. This is equivalent to demeaning the variables by individual i , so $\tilde{Y}_{it} = Y_{it} - \bar{Y}_i$ and $\tilde{X}_{it} = X_{it} - \bar{X}_i$. This is consistent for β if $E[\tilde{\epsilon}_{it} \tilde{X}_{it}] = 0$:

$$\begin{aligned} E[\tilde{\epsilon}_{it} \tilde{X}_{it}] &= E[(\epsilon_{it} - \bar{\epsilon}_i)(X_{it} - \bar{X}_i)] \\ &= E[(\epsilon_{it} - \bar{\epsilon}_i)(X_{it} - \bar{X}_i)] \end{aligned}$$

which holds if there is strict exogeneity of ϵ_{it} , because $\bar{\epsilon}_i$ is a function of future and lag values of ϵ_{it} as well; that is, if X_{it} is uncorrelated with not only ϵ_{it} but also future and lag values of ϵ_{it} .

- (b) Show that estimating $Y_{it} = \alpha_0 + \alpha_1 \bar{X}_i + \beta X_{it} + u_{it}$ yields the same estimate as the LSDV estimator:

By using the F-W-L theorem, estimating the above is equivalent to estimating

$$Y_{it} - \bar{Y} = \alpha_1(\bar{X}_i - \bar{X}) + \beta(X_{it} - \bar{X}) + (u_{it} - \bar{u})$$

That is, regressing the population-demeaned variables on each other without a constant. Applying F-W-L again, note that the annihilator matrix for $\bar{X}_i - \bar{X}$ is

$$M = I - \frac{1}{T \sum_j (\bar{X}_j - \bar{X})^2} [(\bar{X}_i - \bar{X})(\bar{X}_j - \bar{X})]$$

that is, every element of the last term is $(X_i - \bar{X})(X_j - \bar{X})$. Applying the

annihilator matrix to the LHS, the i th element of the LHS vector is

$$\begin{aligned}
(MY)_i &= Y_{it} - \bar{Y} - \frac{(\bar{X}_i - \bar{X}) \sum_{j,t} (\bar{X}_j - \bar{X}) (Y_{jt} - \bar{Y})}{T \sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y} - \frac{(\bar{X}_i - \bar{X}) \sum_j (\bar{X}_j - \bar{X}) \sum_t (Y_{jt} - \bar{Y})}{T \sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y} - \frac{(\bar{X}_i - \bar{X}) \sum_j (\bar{X}_j - \bar{X}) (\bar{Y}_j - \bar{Y})}{\sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y} - \frac{(\bar{X}_i - \bar{X}) \sum_j (\bar{X}_j - \bar{X}) ([a_0 + a_1 \bar{X}_j + \beta \bar{X}_j + \bar{u}_j] - [a_0 + a_1 \bar{X} + \beta \bar{X} + \bar{u}])}{\sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y} - \frac{(\bar{X}_i - \bar{X}) \sum_j (\bar{X}_j - \bar{X}) ((a_1 + \beta)(\bar{X}_j - \bar{X}) + \bar{u}_j - \bar{u})}{\sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y} - (a_1 + \beta)(\bar{X}_i - \bar{X}) - \frac{(\bar{X}_i - \bar{X}) \sum_j (\bar{X}_j - \bar{X}) (\bar{u}_j - \bar{u})}{\sum_j (\bar{X}_j - \bar{X})^2} \\
&= Y_{it} - \bar{Y}_i
\end{aligned}$$

and similar algebra applied to regressing $X_{it} - \bar{X}$ on $\bar{X}_i - \bar{X}$ shows that the full regression is equivalent to regressing $Y_{it} - \bar{Y}_i$ on $X_{it} - \bar{X}_i$, which is the same as LSDV.

- (c) Describe a procedure for testing for zero correlation between the person effects and X_{it} : one could regress T_{it} on \bar{X}_{it} and X_{it} , as before, and t-test the hypothesis that the coefficient on \bar{X}_{it} is 0. If one rejects the hypothesis, then that is evidence for correlation between the person effects and X_{it} .
- (d) Propose estimators for $Var(v_i)$ and $Var(\alpha_i)$:

For $Var(v_i)$, an estimator is the sample variance, given by $\frac{1}{N-1} \sum_i (\hat{\alpha}_i - \hat{\alpha}_0 - \hat{\alpha}_1 \bar{X}_i)^2$, where $\hat{\alpha}$ is taken from the fixed-effects regression and α_0 and α_1 is taken from the regression from part (b).

For $Var(\alpha_i)$, since $\alpha_i = a_0 + a_1 \bar{X}_i + v_i$, the estimator for α_i is $Var(\bar{X}_i) + \hat{Var}(v_i)$.

2) (Event Study)

- (a) See do file.
- (b) See do file and table 1.
- (c) It appears arrests go down in the years following the policy relative just before the curfew was put in place. In the years prior to the policy, arrest rates were fairly flat. However, the estimates are fairly imprecise outside of a couple year band around the policy. Note that data from 10 years before the policy and 10 years after were binned into the -10 and 10 dummies.

- (d) We can restrict our analysis to just look 5 years before and after the policy or 12 years before and after. We can see a slight change in the coefficients but the general pattern is similar—that arrest rates were fairly flat beforehand and decreased in the years after the policy.

- (e) When we add a linear city-specific trend, we get a slightly different story from the data. It appears that arrests were slightly increasing prior to the policy change and then decreased afterwards. Perhaps explaining the impetus for the policy change.

3) (Dynamic Panel)

4) (CRE Event Study)

(a) See do file.

(b) Estimating the model with “mvreg”. See Table 2

(c) To ease notation, let $H \equiv \{85, 87, 88, 89, 90\}$ be the set of event dates.

First, observe that we can write $\pi_{k,t}$ as including the dynamic causal effects as well as the endogenous component. That is, we can write:

$$\pi_{k,t} = \delta_{t-k} \mathbf{1}(t \geq k) + \eta_k$$

As is stated in the original problem, this directly implies the first set of linear restrictions:

$$\pi_{k,t} = \pi_{k,t'} \quad \forall (t, t') < k$$

Next, observe that for all h such that $k, k' \in H$ and for all t and s , we have

$$\begin{aligned} \pi_{k',k'+t} - \pi_{k,k+t} &= \eta_{k'} - \eta_k \\ &= \pi_{k',k'+s} - \pi_{k,k+s} \end{aligned}$$

Similarly, we also have for $k, k' \in H$ and t and s :

$$\begin{aligned} \pi_{k,k+t+s} - \pi_{k,k+t} &= \delta_{t+s} - \delta_t \\ &= \pi_{k',k'+t+s} - \pi_{k',k'+t} \end{aligned}$$

The final set of constraints identify each δ_k separately. For all $k, k' \in H$, for all t, t' and all s :

$$\begin{aligned} \pi_{k,k+s} - \pi_{k,k-t} &= \delta_s \\ &= \pi_{k',k'+s} - \pi_{k',k'-t'} \end{aligned}$$

When we test all these linear restrictions (which collapse to only 26 restrictions from which the remaining restrictions can be derived), we fail to reject the null hypothesis that all the linear restrictions hold. **The p-value of this test is 0.5866.**

- (d) Using the *constraint* function in Stata along with *sureg*, we can estimate the model under the constraints specified in part (c), of which only 26 were needed to span the entire set.¹ These estimates are given in the Table 3

Using *lincom* we can identify each δ_k as the difference $\pi_{85,85+k} - \pi_{85,84}$ which removes the endogenous component appearing in both terms, leaving only the k^{th} dynamic term. See Table 4

Relative to problem (2), we find that the estimates of the initial effect are approximately 3 times as large. Over the subsequent five years, the results for this problem suggest a stable drop of .13. This is approximately a third higher than the estimates that we calculated in problem two for years 1 thru 4. In year five, we estimate that the effect is even larger at .18. However, it should be noted that

¹Note: I did this in a rather brute force manner. Rather than figuring out analytically the minimal set of constraints necessary to span the entire space of constraints, I looped over each of these constraint sets and allowed Stata to remove those that were redundant.

we cannot reject equality of these estimates since we have such large standard errors.

Note that *mvreg* estimates a model of Zellner's Seemingly Unrelated Regression. Thus, although we are allowing for correlation in error terms across equations, our inference requires that for all cities i and j , $Cov(\epsilon_{i,t}, \epsilon_{i,s}) = Cov(\epsilon_{j,t}, \epsilon_{j,s})$. That is, each city is drawn from the same distribution and there is no correlation of the error terms between cities.
