Homework #2

Professor: Pat Kline

Students: Christina Brown, Sam Leone, Peter McCrory, Preston Mui

# 1. Problem 1

Subproblem A

The Delta Method (or the So Called "Delta Method," so called by Dr. James Powell) says that, if we have a random vector  $\theta$  that is asymptotically normal with

$$\sqrt{N}(\hat{\theta} - \theta_0) \stackrel{d}{\to} N(0, \Sigma)$$

then for some  $g(\theta)$  that is continuously differentiable at  $\theta = \theta_0$  with Jacobian matrix

$$G_0 = \frac{\partial g(\theta_0)}{\partial \theta'}$$

we have that  $g(\theta)$  is also asymptotically normal with

$$\sqrt{N}(g(\hat{\theta}) - g(\theta_0) \stackrel{d}{\to} N(0, G_0' \Sigma G_0)$$

In the context of Fehr and Goette (2007), observe that

$$heta = \left( egin{array}{c} ar{Y_A} \\ ar{Y_B} \end{array} 
ight)$$

that

$$\Sigma = \begin{bmatrix} \sigma_{\bar{Y_A}}^2 & \sigma_{\bar{Y_A}} \sigma_{\bar{Y_B}} \\ \sigma_{\bar{Y_A}} \sigma_{\bar{Y_B}} & \sigma_{\bar{Y_B}}^2 \end{bmatrix}$$

and that

$$g(\theta) = \frac{\bar{Y_A} - \bar{Y_B}}{\bar{Y_B}}$$

We can find these values in the reprinted table.  $\bar{Y}_A = 4131.33$ ,  $\bar{Y}_B = 3005.75$ ,  $\sigma_{\bar{Y}_A}^2 = (2669.21)^2$ , and  $\sigma_{\bar{Y}_B}^2 = (2054.20)^2$ . But we still have to do a little bit of work.

Differentiating g with respect to each of its arguments and evaluating them at  $\theta_0$  yields G.

$$G = \begin{pmatrix} \frac{\partial g}{\partial Y_A} = \frac{1}{Y_B} \\ \frac{\partial g}{\partial Y_B} = \frac{-Y_A}{Y_B} \end{pmatrix} \Rightarrow G_0 = \begin{pmatrix} \frac{\partial g(\theta_0)}{\partial Y_A} = \frac{1}{4131.33} \\ \frac{\partial g(\theta_0)}{\partial Y_B} = \frac{-3005.75}{4131.33} \end{pmatrix}$$

The table also gives us  $\sigma_{\bar{Y_A}-\bar{Y_B}}$ , which combined with a simple variance identity, will gives us  $\sigma_{\bar{Y_A}}\sigma_{\bar{Y_B}}$ .

$$\begin{split} VAR(\bar{Y}_{A} - \bar{Y}_{B}) &= VAR(\bar{Y}_{A}) - VAR(\bar{Y}_{B}) - 2COV(\bar{Y}_{A}, \bar{Y}_{B}) \\ \Rightarrow COV(\bar{Y}_{A}, \bar{Y}_{B}) &= \frac{VAR(\bar{Y}_{A}) - VAR(\bar{Y}_{B}) - VAR(\bar{Y}_{A} - \bar{Y}_{B})}{2} \\ \Rightarrow \sigma_{\bar{Y}_{A}}\sigma_{\bar{Y}_{B}} &= \frac{(2669.21)^{2} - (2054.20)^{2} - (519.72)^{2}}{2} \\ \Rightarrow \sigma_{\bar{Y}_{A}}\sigma_{\bar{Y}_{B}} &= 1317417.75 \end{split}$$

Now we can set up the matrix algebra to use the Delta Method to compute an *estimate* of the standard error, S.

$$S^{2} = G'_{0}\Sigma G_{0} = \begin{pmatrix} \frac{\partial g}{\partial \bar{Y}_{A}} & \frac{\partial g}{\partial \bar{Y}_{B}} \end{pmatrix} \begin{bmatrix} \sigma_{\bar{Y}_{A}}^{2} & \sigma_{\bar{Y}_{A}}\sigma_{\bar{Y}_{B}} \\ \sigma_{\bar{Y}_{A}}\sigma_{\bar{Y}_{B}} & \sigma_{\bar{Y}_{B}}^{2} \end{pmatrix} \begin{bmatrix} \frac{\partial g}{\partial \bar{Y}_{A}} \\ \frac{\partial g}{\partial \bar{Y}_{B}} \end{bmatrix}$$

$$\Rightarrow S^{2} = (\frac{\partial g}{\partial \bar{Y}_{A}})[(\frac{\partial g}{\partial \bar{Y}_{A}})(\bar{Y}_{A}^{2}) + (\frac{\partial g}{\partial \bar{Y}_{B}})(\bar{Y}_{B}^{2})] + (\frac{\partial g}{\partial \bar{Y}_{B}})[(\frac{\partial g}{\partial \bar{Y}_{A}})(\sigma_{\bar{Y}_{A}}\sigma_{\bar{Y}_{B}}) + (\frac{\partial g}{\partial \bar{Y}_{B}})(\sigma_{\bar{Y}_{B}}^{2})]$$

$$\Rightarrow S^{2} = \frac{1}{4131.33}[(\frac{1}{4131.33})((2669.21)^{2}) + (\frac{-3005.75}{4131.33})(1317417.75)]$$

$$+ \frac{-3005.75}{4131.33}[(\frac{1}{4131.33})(1317417.75) + (\frac{-3005.75}{4131.33})((2054.20)^{2})]$$

$$\Rightarrow S = 1494.38$$

Subproblem B

Let's rename g to be  $\eta$ . Now we know that

$$\hat{\eta} \sim N(\eta, S)$$

So by the rules of variance,

$$\begin{split} \frac{\hat{\eta}}{.25} &\sim N(\frac{\eta}{.25}, \frac{S}{(.25)^2}) \\ \Rightarrow \frac{\hat{\eta}}{.25} &\sim N(\frac{\eta}{.25}, \frac{1494.38}{(.25)^2}) \\ \Rightarrow \frac{\hat{\eta}}{.25} &\sim N(\frac{\eta}{.25}, 23910.08) \end{split}$$

The experiment's realization of  $\hat{\eta}$  is

$$\hat{\eta} = \frac{\bar{Y}_A - \bar{Y}_B}{\bar{Y}_B} = \frac{4131.33 - 3005.75}{3005.75} = .37$$

Hence producing a 95% confidence interval for  $\frac{\hat{\eta}}{.25}$  is straightforward.

$$\frac{\eta}{.25} \in \left[ \frac{.37}{.25} \pm 1.96(23910.08) \right]$$

$$\Rightarrow \frac{\eta}{.25} \in [-46862.28, 46865.24]$$

This is a huge confidence interval!

This paper published well (in the AER) because it was the first to use an RCT to produce clean estimates for a number of labor supply elasticities. But we think the point of this problem is to show that, perhaps because of the small sample size, the appropriate standard error for the revenue/wage elasticity should leave you with little confidence in that particular result.

# 2. Logit MLE

a) Derive the score of the logit-likelihood: First, noting that

$$\frac{\partial \Lambda(X_i'\beta)}{\partial \beta} = \frac{\exp(X_i'\beta)X_i'(1+X_i'\beta) - \exp(X_i'\beta)\exp(X_i'\beta)X_i'}{(1+\exp(X_i'\beta))^2} = \frac{\exp(X_i'\beta)X_i'}{(1+\exp(X_i'\beta))^2}$$

The sum of the individual score of the logit log-likelihood is therefore

$$s(\beta) = \sum_{i} \frac{Y_{i} \exp(X'_{i}\beta)X'_{i}}{\Lambda(X'_{i}\beta)(1 + \exp(X'_{i}\beta))^{2}} - \frac{(1 - Y_{i}) \exp(X'_{i}\beta)X'_{i}}{(1 - \Lambda(X'_{i}\beta))(1 + \exp(X'_{i}\beta))^{2}}$$

$$= \sum_{i} \left(Y_{i} - (1 - Y_{i}) \exp(X'_{i}\beta)\right) \frac{X'_{i}}{1 + \exp(X'_{i}\beta)}$$

$$= \sum_{i} \left(Y_{i}(1 + \exp(X'_{i}\beta)) - \exp(X'_{i}\beta)\right) \frac{X'_{i}}{1 + \exp(X'_{i}\beta)}$$

$$= \sum_{i} \left(Y_{i} - \frac{\exp(X'_{i}\beta)}{1 + \exp(X'_{i}\beta)}\right)X'_{i}$$

b) The moment condition identifying  $\beta_{ML}$  is

$$E\left[\left(Y_i - \frac{\exp(X_i'\beta)}{1 + \exp(X_i'\beta)}\right)X_i'\right] = 0$$

$$E\left[E[Y_i - \frac{\exp(X_i'\beta)}{1 + \exp(X_i'\beta)}|X_i]X_i'\right] = 0$$

the interpretation here is that the "residual", that is,  $E[Y_i] - \Lambda(X_i'\beta)$ , is uncorrelated with  $X_i$ .  $\Lambda(X_i'\beta)$  can be thought of as the "predicted value" for  $Y_i$ , since  $P(Y_i = 1|X_i) = \Lambda(X_i'\beta)$ .

c) The moment conditions identifying  $\beta_{NLLS}$  are

$$0 = E \left[ -2(Y_i - \Lambda(X_i'\beta)) \frac{\exp(X_i'\beta)}{(1 + \exp(X_i'\beta))^2} X_i' \right]$$
$$= E \left[ E[(Y - \Lambda(X_i'\beta)) | X_i] \frac{\exp(X_i'\beta)}{(1 + \exp(X_i'\beta))^2} X_i' \right]$$

- d) Under which conditions does  $\beta_{NLLS}$  coincide with  $\beta_{ML}$ ? The moment conditions will coincide when  $E[Y_i \Lambda(X_i'\beta)|X_i'] = 0$  for all  $X_i$ ; that is, they coincide when the logit model is correctly specified, and  $\Lambda(X_i'\beta)$  is the actual conditional expectation function of  $Y_i$  given  $X_i$ .
- e) Under proper specification of the model, the asymptotic variance of the estimator is the additive inverse of the inverse of expectation of the Hessian of the log likelihood.<sup>1</sup> As was derived in part a), the score (i.e. the gradient of the log-likelihood) is

$$s(X_i, \beta) = \left(Y_i - \frac{\exp(X_i'\beta)}{1 + \exp(X_i'\beta)}\right) X_i'$$

Thus, the Hessian matrix is

$$\nabla_{\beta} s(X_i, \beta) = -\frac{\exp(X_i'\beta)(1 + \exp(X_i'\beta)) - \exp(X_i'\beta)^2}{(1 + \exp(X_i'\beta))^2} X_i X_i'$$
$$= -\frac{\exp(X_i'\beta)}{(1 + \exp(X_i'\beta))^2} X_i X_i'$$

<sup>&</sup>lt;sup>1</sup>I just wanted to write that all out.

And so, the asymptotic variance of  $\beta_{ML}$  under correct specification is given by

$$\sqrt{N}(\beta_{ML} - \beta) \stackrel{d}{\to} \mathcal{N}(0, H(\beta)^{-1})$$

with

$$H(\beta) = E\left[\frac{\exp(X_i'\beta)}{(1 + \exp(X_i'\beta))^2} X_i X_i'\right]$$

f) Let  $V_s = E[s(X_i, \beta)s(X_i, \beta)']$ , the outer product of the score. Under mispecification, the asymptotic variance of  $\beta_{ML}$  is as follows:

$$\sqrt{N}(\beta_{ML} - \beta) \xrightarrow{d} \mathcal{N}\left(0, H(\beta)^{-1} V_s H(\beta)^{-1}\right)$$

with  $H(\beta)$  defined as in the previous problem and

$$V_s = E\left[\left(Y_i - \frac{\exp(X_i'\beta)}{1 + \exp(X_i'\beta)}\right)^2 X_i X_i'\right]$$

g) Suppose the data are independent across but not necessarily within clusters. Propose a cluster robust estimator of the asymptotic variance of  $\beta_{ML}$ 

One idea is to construct a similar estimator to the one we have for cluster robust standard errors for OLS:

$$\frac{J}{J-K} \frac{1}{N} \left( \frac{1}{N} \sum_{i=1}^{N} \frac{\exp(X_i'\beta)}{(1+\exp(X_i'\beta))^2} X_i' X_i \right)^{-1} \left( \frac{1}{N} \sum_{j=1}^{J} X_j u_j u_j' X_j' \right) \left( \frac{1}{N} \sum_{i=1}^{N} \frac{\exp(X_i'\beta)}{(1+\exp(X_i'\beta))^2} X_i' X_i \right)^{-1}$$

where

$$u_j = \left[ \left( Y_s - \frac{\exp(X_s'\beta)}{(1 + \exp(X_s'\beta))^2} \right) \right]_{s \in j}.$$

That is,  $u_j$  is the vector of "residuals" for observations s in cluster j.

## 3. Matlab Probit DGP

- a) (Matlab program attached)
- b) The ML point estimates of  $\hat{\beta}^{con} = (\hat{\alpha}, \hat{b})$  are (-0.0175, 0.9159). The standard errors are (0.3030, 0.3607), respectively.
- c) Score test: Following Wooldridge (2010), page 570, the LM statistic is the ESS from the following regression

$$\frac{\hat{u}_i}{\sqrt{\hat{G}_i(1-\hat{G}_i)}} = \alpha \frac{\hat{g}_i}{\sqrt{\hat{G}_i(1-\hat{G}_i)}} x_i + \gamma \frac{\hat{g}_i}{\sqrt{\hat{G}_i(1-\hat{G}_i)}} z_i$$

where  $x_i$  is the regressor matrix in the unconstrained regression (constant and X) and  $z_i$  is the vector of  $X_i^2$ . The ESS from this regression was 0.2963, which has a p-value of 0.58621. So, one does not reject the null that  $b_2 = 0$ .

d) The unrestricted model yields point estimates of  $\hat{\beta}^{unc} = (\hat{\alpha}, \hat{b}, \hat{b_2}) = (-0.0435, 0.9175, 0.0428)$ . The Wald test will test the null  $g(\beta) = 0$  where

$$g(\beta) \equiv (0, 0, 1) \cdot \beta = b_2$$
$$G(\beta) \equiv \frac{\partial g(\beta)}{\partial \beta} = (0, 0, 1)$$

and the Wald statistic is given by

$$N \cdot \hat{b_2} \cdot \left(G \cdot \frac{1}{\sqrt{N}} H^{-1} \cdot G'\right)^{-1} \cdot \hat{b_2}$$

where H is the average Hessian at the ML estimate. Because we know that the model is correctly specified, I use the inverse Hessian instead of the sandwich estimator. The Wald evaluates to 7.4592, which has a p-value of 0.0063 under the  $\chi^2$  distribution with d.f. 1, so one rejects the null that  $b_2 = 0$ . This is starkly different from the score test result, which did not reject the null. This makes sense, as the Wald tends to reject more than the LM test. If one bumps the number of observations up (say, to 5000), both tests reject the null.

#### 4. Clustered DGP in Stata

a) Regressing  $Y_{ic}$  on  $D_{ic}$ , we get the results in table 1.

Table 1: Clustered DGP

	(1)	(2)	(3)
	Y_ic, Regular SE	Y_ic, Robust SE	Y_ic, Clustered SE
$d_i$	1.010***	1.010***	1.010***
	(0.03237)	(0.03244)	(0.09508)
Constant	0.0394*	0.0394*	0.0394
	(0.02278)	(0.02037)	(0.10761)
$R^2$	0.089	0.089	0.089
Observations	10000	10000	10000

Standard errors in parentheses

The basic SE are 0.03237. The standard errors are slightly larger (0.03244) when we correct for heteroskedasticity in column 2 and significantly larger (0.09508) when we account for the intracluster correlation of observations from the same cluster.

b) Changing  $\sigma_{\eta}^2$  to 0. Regressing  $Y_{ic}$  on  $D_{ic}$ , we get the results in table :

The standard errors are fairly similar for columns 1 and 2 to what we had in A. They are 0.02732 for the regular SE, 0.027731 for robust SE. The clustered SE (0.02420) are similar to the magnitude of the non-clustered version.

<sup>\*</sup> p<0.10, \*\* p<0.05, \*\*\* p<0.01

Table 2: Clustered DGP

	(1)	(2)	(3)
	Y_ic, Regular SE	Y_ic, Robust SE	Y_ic, Clustered SE
d_ic	0.992***	0.992***	0.992***
	(0.02732)	(0.02731)	(0.02420)
Constant	-0.00105	-0.00105	-0.00105
	(0.01911)	(0.01923)	(0.09650)
$R^2$	0.117	0.117	0.117
Observations	10000	10000	10000

Standard errors in parentheses

- c) Comment on your differences in the answers to a) and b). The SE are fairly similar in columns 1 and 2 for parts a) and b) though they are slightly smaller in part b as a result of the lower variance of  $y_{ic}$  in part b. In part b since there is no intra-cluster correlation in the coefficient on  $d_{ic}$  the clustered standard errors are of a similar magnitude to the non-clustered version (0.02420).
- d) In table 3, we see that the simulation rejects the null that the coefficient on  $d_{ic}=157\%$  of the time when we don't cluster our standard errors and about 5% (which we would expect) when we cluster. So the non-clustered version is rejecting too often and the clustered version is rejecting at about the rate of p which we set.

Table 3: Monte Carlo Simulations

			(1)		
	count	mean	$\operatorname{sd}$	min	max
reject	1000	.567	.4957386	0	1
$reject\_cluster$	1000	.055	.2280943	0	1

- e) Here we have that the regression with non-clustered standard errors rejects the test that the coefficient equals the average of the cluster level  $\eta$ 's 3% of the time and the clustered standard errors are never rejecting, so in this case clustering is causing us not reject often enough.
- f) When treatment is at the cluster level like in the case of the set up for part d then clustering standard errors will produce the accurate standard errors. However, in e, when the treatment is at the individual level but those individuals are within a cluster, for example a school or village then clustering the errors will actually cause our standard errors to be larger than we would want, leading to us to not reject enough. For the purpose of the internal validity of the study, using non-clustered standard errors when treatment is at the individual level is appropriate.

<sup>\*</sup> p<0.10, \*\* p<0.05, \*\*\* p<0.01

Table 4: Monte Carlo Simulations

			(1)		
	count	mean	$\operatorname{sd}$	min	max
reject	1000	.03	.1706726	0	1
$\_reject\_cluster$	1000	0	0	0	0

#### 5. CPS and WLS

- a) See results in column 1 of table 5.
- b) Collapsed results used in analysis below.
- c) See column 2 of table 5. The coefficients are identical (as we would expect) but the standard errors are much smaller when we weight by bin size.
- d) If wages are *iid* within a cell, then the variance of each cell is  $\sigma^2/N_c$  where  $\sigma^2$  is the population variance and  $N_c$  is the number of observations in the cell.
- e) Formula above is used to calculate the variance of the cell means.
- f) See results in column 3 of table 5.
- g) With an RSS of 0.133 and 38 degrees of freedom we are not able to reject this model at the 5% level. In other words we cannot reject our model explains the data up to a sampling error.
- h) See results in table 7.
- i) With an RSS of 0.009 and 15 degrees of freedom we cannot reject this goodness of fit of this model at the 5% level either.
- j) See fig. 1. The model does a very nice job of fitting the data. The place it has a bit of trouble fitting is for older more educated individuals. The model overestimates the wages of 65+ males with some college and underestimates the wages for males with a BA or more.
- k) A simple model which passes the chi-squared test is just lnwage on sex. We cannot reject that this model explains all of the variation in lnwage up to a sampling error.

### 6. Random Coefficient Binary Choice Model:

a) As was derived in the lecture notes, the simulated log likelihood can be derived as follows. Denote the Logistic cdf with  $\Lambda$  and its pdf with  $\lambda$ .

First observe that

$$Pr(Y_i = 1 | X_i, b_i) = Pr(\epsilon_i > -b_i x_i) = 1 - Pr(\epsilon_i < -b_i x_i) = 1 - \Lambda(-b_i x_i) = \Lambda(b_i x_i)$$

Thus, assuming that  $b_i$  and  $\epsilon_i$  are independent:

$$Pr(Y_i = 1|X_i) = \int \Lambda(bx_i) \frac{1}{\sigma} \phi(\frac{b_i - \mu}{\sigma}) db$$

The likelihood of this model for a single observation is

$$L(Y_i, X_i; \mu, \sigma) = \left(\int \Lambda(bx_i) \frac{1}{\sigma} \phi(\frac{b_i - \mu}{\sigma}) db\right)^{Y_i} \left(1 - \int \Lambda(bx_i) \frac{1}{\sigma} \phi(\frac{b_i - \mu}{\sigma}) db\right)^{1 - Y_i}$$

Thus, for **fixed** random draws  $\{u_i\}_{m=1}^M$  from  $\mathcal{N}(0,1)$ , the simulated likelihood is

$$\hat{L}_{M}(Y_{i}, X_{i}, \mu, \sigma) = \left(\frac{1}{M} \sum_{m=1}^{M} \Lambda(\underbrace{(\mu + \sigma u_{im})}_{\equiv b} X_{i})\right)^{Y_{i}} \left(1 - \frac{1}{M} \sum_{m=1}^{M} \Lambda(\underbrace{(\mu + \sigma u_{im})}_{\equiv b} X_{i})\right)^{1 - Y_{i}}$$

Clearly, taking logs (of the product of all the likelihoods) allows us to recover the simulated log-likelihood of the full sample.

Let's differentiate with respect to  $\mu$  and  $\sigma$ !

For  $\mu$ :

$$\begin{split} &\frac{\partial}{\partial \mu} \frac{1}{N} \sum_{i}^{N} Y_{i} log \left( \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i}) \right) + (1 - Y_{i}) log \left( 1 - \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i}) \right) \\ &= \frac{1}{N} \sum_{i}^{N} \left[ \frac{Y_{i} X_{i} \frac{1}{M} \sum_{m=1}^{M} \lambda((\mu + \sigma u_{im}) X_{i})}{\frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i})} - \frac{(1 - Y_{i}) X_{i} \frac{1}{M} \sum_{m=1}^{M} \lambda((\mu + \sigma u_{im}) X_{i})}{1 - \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i})} \right] \end{split}$$

For  $\sigma$ :

$$\begin{split} & \frac{\partial}{\partial \sigma} \frac{1}{N} \sum_{i}^{N} Y_{i} log \left( \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i}) \right) + (1 - Y_{i}) log \left( 1 - \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i}) \right) \\ & = \frac{1}{N} \sum_{i}^{N} \left[ \frac{Y_{i} X_{i} \frac{1}{M} \sum_{m=1}^{M} \lambda((\mu + \sigma u_{im}) X_{i}) u_{im}}{\frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i})} - \frac{(1 - Y_{i}) X_{i} \frac{1}{M} \sum_{m=1}^{M} \lambda((\mu + \sigma u_{im}) X_{i}) u_{im}}{1 - \frac{1}{M} \sum_{m=1}^{M} \Lambda((\mu + \sigma u_{im}) X_{i})} \right] \end{split}$$

- b) See  $max \ sml.m$  file.
- c) See  $max \ sml.m$  file.

d) These results are invariant to initial conditions:

$$\begin{bmatrix} \mu \\ ln(\sigma) \end{bmatrix} = \begin{bmatrix} 1.6011 \\ 0.5139 \end{bmatrix}$$

e) Let  $\hat{\theta}_{MSL}$  denote the estimated parameters from the method of simulated likelihood and the true parameters  $\theta = [\mu, \sigma]'$ . Under proper specification, we know that

$$\sqrt{N}(\hat{\theta}_{MSL} - \theta) \to \mathcal{N}(\mathbf{0}, \mathbf{H}(\theta)^{-1})$$

By the delta-method, with  $g(\theta) \equiv [\mu ln(\sigma)]'$ , we have that

$$\sqrt{N}(g(\hat{\theta}_{MSL}) - g(\theta)) \to \mathcal{N}(\mathbf{0}, \mathbf{GH}(\theta)^{-1}\mathbf{G})$$

where

$$\mathbf{G} \equiv \frac{\partial g(\theta)}{\partial \theta} = \begin{bmatrix} 1 & 0 \\ 0 & \frac{1}{\sigma} \end{bmatrix}$$

When we calculate the square root of the diagonal elements of  $\frac{1}{N}\mathbf{H}(\hat{\theta})^{-1}$ , we derive the standard errors of our estimates of  $\mu$  and  $\ln(\sigma)$ : (0.2633, 0.3884).

f) To calculate the standard errors for the incorrect model, we replace  $\mathbf{H}(\theta)^{-1}$  with  $\mathbf{H}(\theta)^{-1}\mathbf{V_s}\mathbf{H}(\theta)^{-1}$ , where  $\mathbf{V_s}$  is the population variance-covariance matrix of the scores—defined by the the criterion function we are maximizing.

Again, we use the analogy principle to replace the asymptotic variance terms with the simulated likelihood, sample averages. This yields standard errors of  $\mu$  and  $ln(\sigma)$ : (0.4839, 0.6417).
